

Current Frequency Spectral Subtraction and Its Contribution to Induction Machines' Bearings Condition Monitoring

El Houssin El Bouchikhi, Vincent Choqueuse, *Member, IEEE*,
and Mohamed El Hachemi Benbouzid, *Senior Member, IEEE*

Abstract—Induction machines are widely used in industrial applications. Safety, reliability, efficiency, and performance are major concerns that direct the research activities in the field of electrical machines. Even though the induction machine is very reliable, many failures can occur such as bearing faults, air-gap eccentricity, and broken rotor bars. The challenge is, therefore, to detect them at an early stage in order to prevent breakdowns. In particular, stator current-based condition monitoring is an extensively investigated field for cost and maintenance savings. In this context, this paper deals with the assessment of a new stator current-based fault detection approach. Indeed, it is proposed to monitor induction machine bearings by means of stator current spectral subtraction, which is performed using short-time Fourier transform or discrete wavelet transform. In addition, diagnosis index based on the subtraction residue energy is proposed. The proposed bearing faults condition monitoring approach is assessed using simulations, issued from a coupled electromagnetic circuits approach-based simulation tool, and experiments on a 0.75-kW induction machine test bed.

Index Terms—Bearing fault, fault detection, induction machines, signal processing, spectral subtraction.

NOMENCLATURE

$STFT$	Short-time Fourier transform.
PSD	Power spectral density.
DWT	Discrete wavelet transform.
$[\cdot]^{-1}$	Matrix inverse.
$[\cdot]^T$	Matrix transpose.
$[I_r]$	Rotor current vector.
$[I_s]$	Stator current vector.
$[L_{rr}]$	Rotor windings self and mutual inductances.
$[L_{rs}]$	Mutual inductances between rotor windings and stator ones.
$[L_{sr}]$	Mutual inductances between stator windings and rotor ones.
$[L_{ss}]$	Stator windings self and mutual inductances.
$[R_r]$	Cage resistances matrix.
$[R_s]$	Diagonal matrix of stator phases resistances.

I. INTRODUCTION

NOWADAYS, induction machines are widely used in industrial applications. In fact, induction machines are still the most important rotating electric machines in industry mainly because of their low price, ruggedness, efficiency, and reliability. Despite its robustness, this machine can be subjected to various failures that can broadly be classified as follows [1]:

- 1) stator faults: opening or shorting of one or more of a stator phase winding;
- 2) broken rotor bar or cracked rotor end-rings;
- 3) static and/or dynamic air-gap irregularities;
- 4) bent shaft;
- 5) bearing and gearbox failures.

The distribution of these failures within the machine sub-assemblies is reported in many reliability survey [2], [3]. Depending on the type and size of the machine, bearing faults distributions among all faults vary from 40% to 90% from large to small machines.

Therefore, a permanent condition monitoring of the induction machine is of high interest since it contributes to minimize the downtime and improves its reliability and availability. Early diagnosis of these faults is an extensively investigated field for cost and maintenance savings. Traditionally, the machine state can be supervised using different strategies such as vibration monitoring, temperature measurements, flux monitoring,

model and artificial intelligence-based techniques [4], [5]. Motor current signature analysis for incipient fault detection has received much attention in recent years [2]. These techniques are based on the use of three-phase currents that are already measured in the drive system for other purposes such as control and protection.

Previous works have focused on the use of signal processing tools for stator current postprocessing in order to detect a characteristic fault frequencies in both stationary (steady state) and nonstationary (transient, variable speed, load oscillation, etc.) operating conditions. In stationary environment, most studies perform stator current spectral analysis using the periodogram, and its extensions based on the Fourier Transform [1], [6]–[8]. In order to improve the frequency resolution many high resolution techniques have been used such as the MUSIC algorithm [9], [10]. In nonstationary conditions, time frequency [11]–[13] and time scale [14] techniques were proposed. Although these techniques lead to good representations, they require a feature extraction and a classification steps in order to distinguish a faulty machine from a healthy one and afterward measure fault severity.

This paper proposes a fault-detection technique that takes into account some of the earlier discussed aspects [15]. The proposed technique is based on stator current frequency spectral subtraction. More precisely, the proposed approach is based on the *STFT* and allows to directly derive a fault criterion. The fault criterion is of high interest since it conveys the information about the presence of the fault and its severity.

The major contributions of this paper are as follows:

- 1) an intuitive stator current-based fault-detection approach;
- 2) a reliable and robust fault criterion for bearing fault detection.

It is organized as follows: the proposed technique is presented in Section II. In Section III, a short overview of bearing fault types and their effects on induction machine stator current is given. Then, the performances of the proposed approach on simulated data, issued from a coupled electromagnetic circuits approach-based simulation tool, are discussed. Finally, experimental results for several bearing faults are reported in Section IV to validate the feasibility of the *STFT*-based spectral subtraction, which is compared with DWT-based spectral subtraction. Section V concludes this paper and gives some prospects for further investigations.

II. SPECTRAL SUBTRACTION

A. Fault Detection Algorithm

Spectral subtraction is broadly used in audio data processing in order to remove acoustic noise and for speech enhancement [16]–[18]. Up to now, for fault detection, the spectral subtraction was only used as a denoising method. This pre-processing step allows to improve robustness against noise of failure indicators in electrical drives [19], [20]. Afterward, advanced signal processing techniques are used to detect electrical machine abnormal operating conditions. Fig. 1 shows flowcharts illustrating the main differences between the classical technique [20] [see Fig. 1(a)] and the proposed one [see

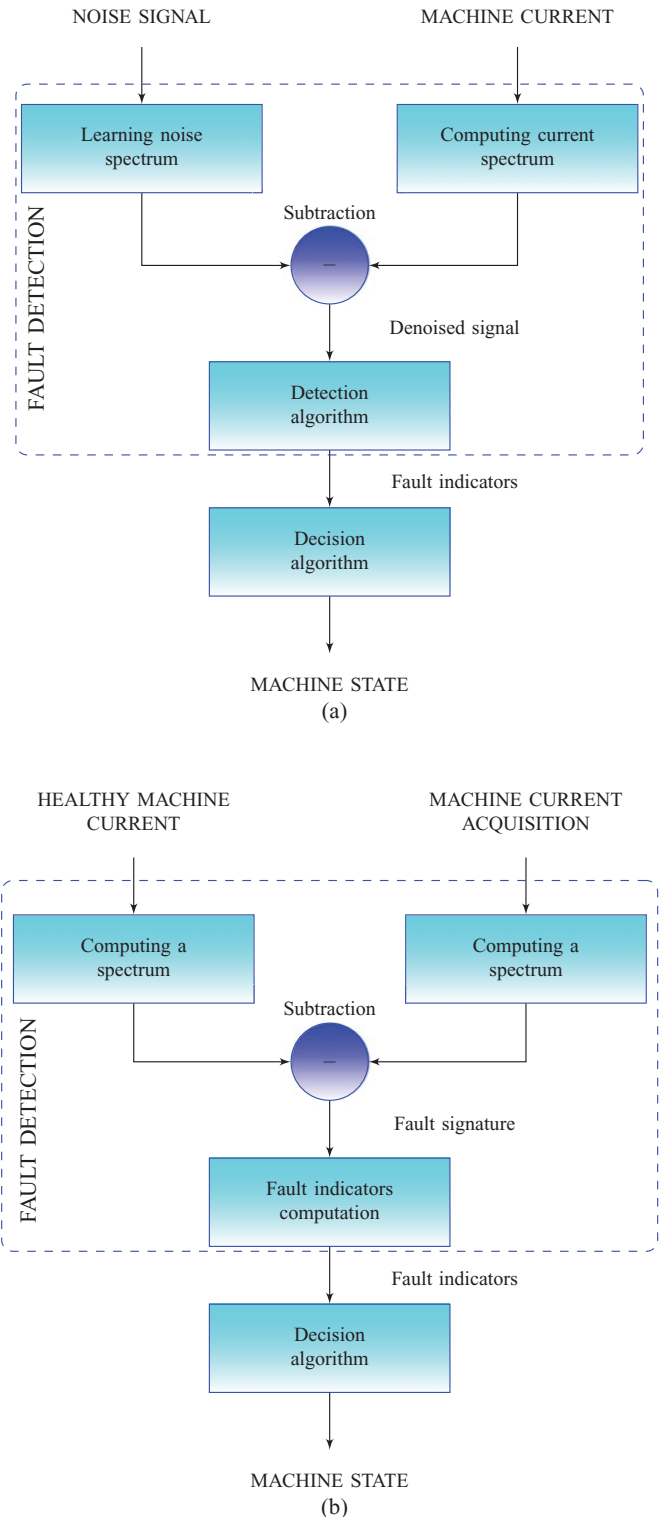

Fig. 1. Spectral subtraction flowchart for fault-detection approach. (a) Spectral subtraction for denoising aims. (b) Proposed approach.

Fig. 1(b)]. In fact, in this paper, we propose to use spectral subtraction as the main tool for induction machines fault diagnosis. In particular, it is used for bearing faults detection using stator current. The proposed technique is well-suited for steady state and constant speed induction machine operating conditions. It is

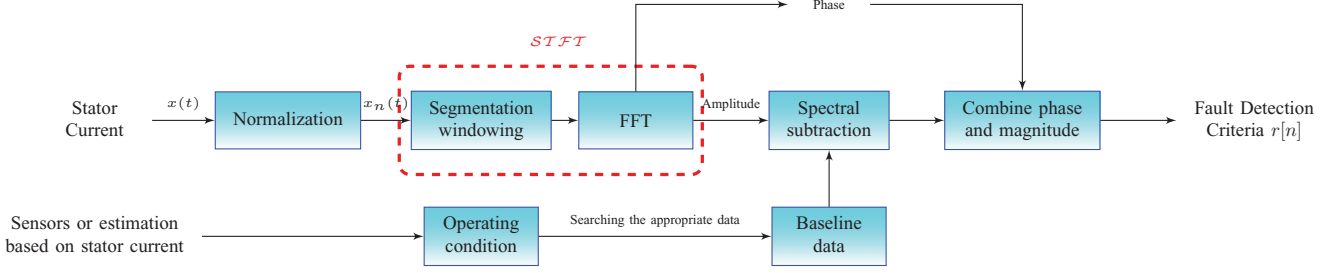

Fig. 2. Block diagram of the proposed FFT-based spectral subtraction faults-detection algorithm.

only applied on stationary signals, which means time independent frequency content. In this context, the proposed strategy allows the fault-effect extraction from the stator current by subtracting the PSD of the healthy machine from the faulty machine one for each time step.

The proposed technique is based on the following steps.

- 1) Spectral estimation of the healthy signal $x_h[n]$ (baseline data) based on the $(STFT)$. The $STFT$ of $x_h[n]$ is defined as

$$X_h(m, \omega) = \sum_{n=0}^{N-1} x_h[n] w[n-m] e^{-j\omega n} \quad (1)$$

where $w[n]$ is the window function and N is the number of samples. $m \in \Omega$ corresponds to the time index.

Finally, the spectrum of the healthy signal is computed by averaging the $STFT$ with respect to time

$$\mu(\omega) = \frac{1}{|\Omega|} \sum_{m \in \Omega} |X_h(m, \omega)| \quad (2)$$

where $|\Omega|$ denotes the cardinal of the set Ω . This first step is equivalent to the computation of the Welch periodogram [21].

- 2) Spectral estimation of the supervised machine stator current signal $x_s[n]$ using $STFT$ (3). The $STFT$ of $x_s[n]$ is defined as

$$X_s(m, \omega) = \sum_{n=0}^{M-1} x_s[n] w[n-m] e^{-j\omega n} \quad (3)$$

where $w[n]$ has been defined previously and M is the number of samples.

- 3) Subtraction of the current spectrum of the healthy case from the monitored machine current spectrum at each time m

$$R(m, \omega) = ||X_s(m, \omega)| - \mu(\omega)| e^{j\varphi(m, \omega)} \forall m \quad (4)$$

where $\varphi(m, \omega) = \angle(X_h(m, \omega))$ and \angle is the angle of the complex number X_h .

- 4) Performing the inverse $STFT$ to reconstruct the temporal signal $r[n]$ from $R(m, \omega)$ with the overlap-add algorithm [22].
- 5) Computation of the fault indicator.

The spectral subtraction for fault detection is an easy way to extract the fault effect on the stator current. Fig. 2 shows then the proposed FFT-based spectral subtraction faults-detection algo-

rithm. It clearly illustrates the importance of the operating condition measurement in order to choose the appropriate healthy state condition signal from the database. Once the healthy state condition signal is obtained, it is subtracted from the acquired signal in order to diagnose the machine condition. Furthermore, the proposed approach is simple to implement since it is based on the Fourier transform which makes it very attractive for industrial applications. In fact, most DSP-boards include functions for DFT computation. Moreover, the DFT can be efficiently computed using the FFT.

The next section deals with the criteria chosen as fault indicator.

B. Fault Detection Criteria

For an automatic fault detection, we propose two criteria based on the results of the stator current spectral subtraction. These criteria are the fault signature energy \mathcal{E} and the fault signature energy to healthy case energy ratio \mathcal{R} .

$$\begin{cases} \mathcal{E} = \frac{1}{N} \sum_{n=0}^{N-1} |r[n]|^2 \\ \mathcal{R} = \frac{\sum_{n=0}^{N-1} |r[n]|^2}{\sum_{n=0}^{N-1} |x_h[n]|^2} \end{cases} \quad (5)$$

In addition, to highlight the machine healthy state, the previous criteria have also been used to estimate the fault severity degree.

Fig. 3 summarizes the proposed fault-severity estimation algorithm.

III. SIMULATION RESULTS

This section reports on the performance of the proposed approach on simulated data. Simulation were performed using a coupled electromagnetic circuits induction machine model. In particular, eccentricity fault introduced by bearing failures have been simulated and stator current signal has been sampled and processed according to the previously presented algorithm.

A. Coupled Electromagnetic Circuits Machine Modeling Briefly

The coupled electromagnetic circuits approach combined with the arbitrary reference frames theory is the theoretical groundwork for modeling induction machines [24]. An induction machine is considered as a highly symmetrical

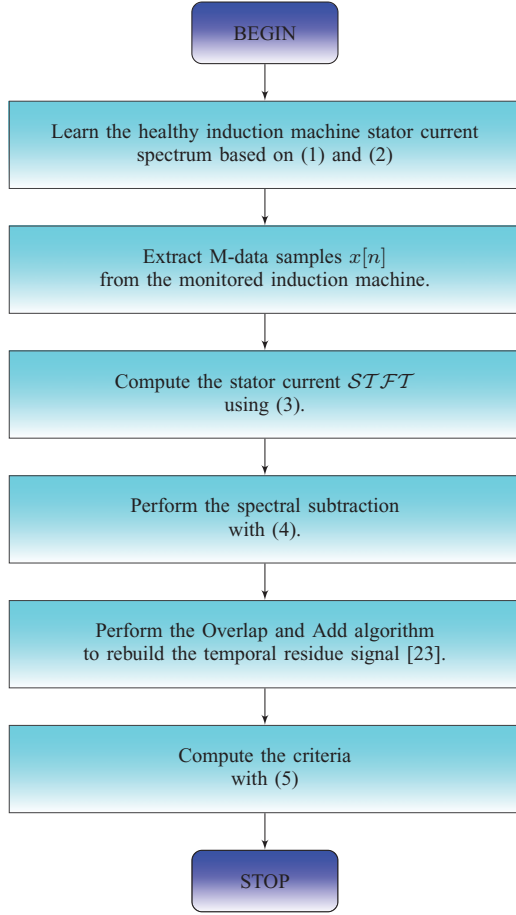

Fig. 3. Spectral subtraction-based fault severity criteria algorithm.

electromagnetic system. Any fault will therefore induce a certain degree of asymmetry [25]. In this context, a MATLAB–Simulink-based tool of faulty induction machines has been developed to generate a fault database and therefore allow testing different stator current-based fault detection technique [26].

In this modeling context, the representation of an induction machine with a cage rotor is fundamentally the same as one with a phase wound rotor, where it is assumed that the cage rotor can be replaced by a set of mutually coupled loops as shown by Fig. 4.

The dealt with approach is based on the induction machine analytical models. Inductances are calculated from the actual geometry and winding layout of the machine.

The induction machine electrical and mechanical equation system is given by

$$\begin{cases} \frac{d}{dt}[I] = -[L]^{-1} \left([R] + \Omega \frac{d}{d\theta_m} [L] \right) [I] + [L]^{-1} [V] \\ \frac{d}{dt}\Omega = \frac{1}{2J} [I]^T \left(\frac{d}{d\theta_m} [L] \right) [I] - \frac{f}{J} \Omega - \frac{1}{J} \Gamma_C \\ \frac{d}{dt}\theta_m = \Omega \end{cases} \quad (6)$$

Fig. 4. Equivalent circuit of a cage rotor showing rotor loops and circulating end-ring current.

Fig. 5. Bearing structure with main dimensions.

where

$$\begin{aligned} [V] &= \begin{bmatrix} [V_s] \\ [0] \end{bmatrix} & [I] &= \begin{bmatrix} [I_s] \\ [I_r] \end{bmatrix} \\ [R] &= \begin{bmatrix} [R_s] & [0] \\ [0] & [R_r] \end{bmatrix} & [L] &= \begin{bmatrix} [L_{ss}] & [L_{sr}] \\ [L_{rs}] & [L_{rr}] \end{bmatrix}. \end{aligned}$$

All the relevant inductances matrices $[L]$ are calculated using the winding function method [27].

B. Bearing Faults Detection

1) *Bearing Fault Impact on Induction Machine Stator Current:* Vibration analysis is one of the most extended condition monitoring techniques for bearing fault diagnosis. Bearings defects have been typically categorized as distributed or local. Local defects cause periodic impulses in vibration signals. Amplitude and frequency of such impulses are determined by shaft rotational speed, fault location, and bearing dimensions

(see Fig. 5). The frequencies of these impulses are given as

$$\begin{cases} f_c = \frac{f_s}{2} \left(1 - \frac{d}{D} \cos(\alpha) \right) \\ f_{bd} = \frac{D}{d} f_s \left(1 - \frac{d^2}{D^2} \cos^2(\alpha) \right) \\ f_{id} = \frac{n f_s}{2} \left(1 - \frac{d}{D} \cos(\alpha) \right) \\ f_{od} = \frac{n f_s}{2d} \left(1 - \frac{d}{D} \cos(\alpha) \right) \end{cases} \quad (7)$$

In [28] and [29], it has been demonstrated that the characteristic bearing fault frequencies in vibration can be reflected on stator currents. Since ball bearings support the rotor, any bearing defect will produce a radial motion between the rotor and the stator of the machine (air-gap eccentricity), which may lead to anomalies in the air-gap flux density. As the stator current for a given phase is linked to flux density, the stator current is affected as well by the bearing defect. The relationship between vibration frequencies and current frequencies for bearing faults can be described by (8). Therefore, by means of (8), it is possible to analyze the specific fault subharmonics in order to find abnormalities in their amplitude values

$$f_{bnq} = |f_s \mp k f_d| \quad (8)$$

where $k = 1, 2, 3, \dots$ and f_d is one of the characteristic vibration frequencies given earlier.

It is well established that for bearing single-point defects, the characteristic stator-current-fault frequencies are good fault indicators [29], [30]. This model has been applied in several works dealing with bearing faults detection. It has also been demonstrated that these bearings faults have an effect over the machine eccentricity and/or load variations. Therefore, the analysis of stator current fundamental sidebands, in order to detect eccentricity or load variations, can also be useful for bearing diagnosis. The aforementioned bearing faults model components are analyzed using spectral analysis in [31]. In [32] and [33] time-frequency and time-scale methods are used to identify bearing faults by analyzing stator current based on the same model.

In this section, the approach in [29] has been adopted to model bearing failure effects on induction machine stator current. In particular, static and mixed eccentricities were used to emulate bearing faults in the induction machine.

Stator current signals have been simulated using coupled electromagnetic approach during 2 s at 10 kHz sampling rate with 10% static and mixed eccentricities. Simulation results are given in Fig. 6. It is obvious that static and mixed eccentricities (modeling the bearing fault) introduce sidebands on the stator current. It should be stressed that the discrimination of the defected component requires explicit knowledge of the bearing geometry.

2) *Static eccentricity detection using spectral subtraction:* In this case, Fig. 7(a) shows the induction machine stator current for healthy and faulty conditions. Fig. 7(b) illustrates then the spectral subtraction results. It is therefore obvious, that the simulated fault is clearly highlighted by the proposed approach. Moreover, the achieved results prove the effectiveness of

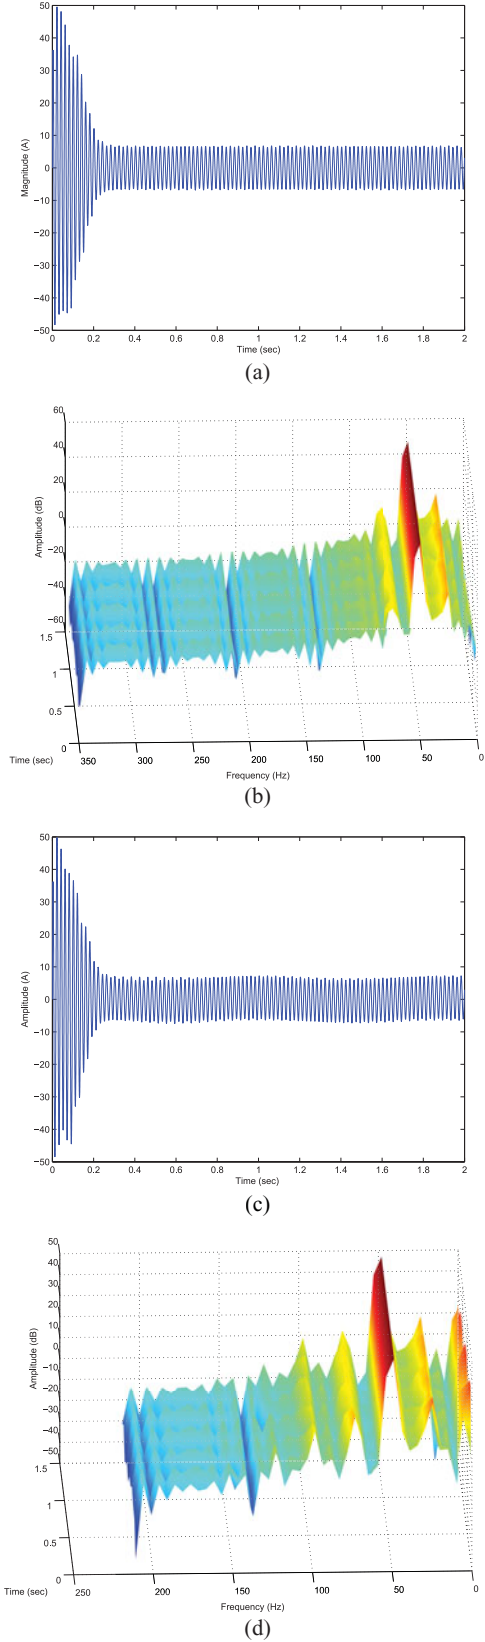

Fig. 6. Faulty induction machine simulation signals. (a) Induction machine stator current with static eccentricity. (b) Faulty induction machine stator current spectrogram. (c) Induction machine stator current with mixed eccentricity. (d) Faulty induction machine stator current spectrogram.

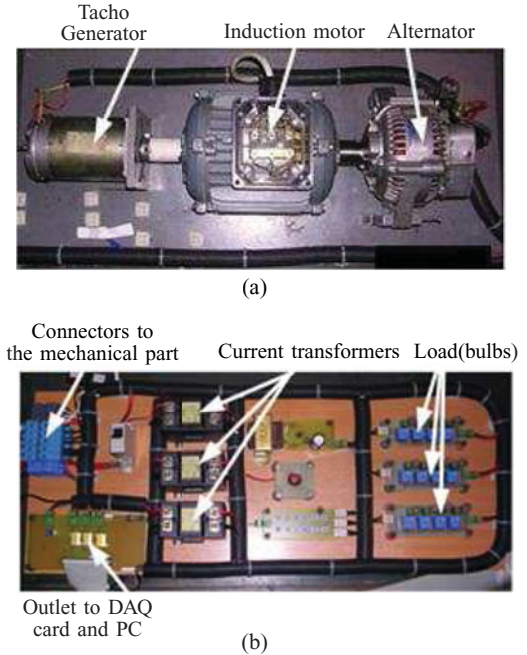

Fig. 8. Test rig. (a) Mechanical part. (b) Electrical part.

monitoring the amplitudes of fundamental sidebands for fault detection in induction machine.

3) *Mixed eccentricity detection using spectral subtraction:* The same conclusions are drawn in the second case with Fig. 7(c) and (d), respectively, illustrating the induction machine stator current and the spectral subtraction result.

To summarize the simulation results, it should be mentioned that the proposed spectral subtraction-based fault-detection approach is effective in terms of fault impact extraction from the stator current. Indeed, this impact is obvious and clearly highlights the occurrence of a fault within the induction machine [see Fig. 7(b) and (d)].

IV. EXPERIMENTAL TESTS

A conventional 0.75-kW induction machine drive test rig is used in order to test the proposed spectral subtraction-based fault-detection approach (see Fig. 8).

A. Test Rig

The test rig mechanical part [see Fig. 8(a)] is composed of a synchronous machine and an induction machine. The induction machine is fed by the synchronous generator in order to eliminate time harmonics. Indeed, this will automatically eliminate supply harmonics, and therefore allow focusing only on bearing faults effect on the stator current.

The induction machine has two 6204.2ZR type bearings (single row and deep groove ball bearings) with the following parameters: outside diameter is 47 mm, inside one is 20 mm, and pitch diameter $D = 31.85$ mm. A bearing has 8 balls ($n = 8$) with an approximate diameter of 12 mm and a contact angle of $\alpha = 0^\circ$.

Fig. 9. Artificially deteriorated bearing: (a) outer-race deterioration, (b) inner-race deterioration, (c) cage deterioration, and (d) ball deterioration.

TABLE I
FAULT DETECTION CRITERIA FOR BALL BEARING FAULT

Criterion	\mathcal{R} (10^{-4})		\mathcal{E} (10^{-4})	
Bearing	Healthy	Faulty	Healthy	Faulty
No load	2.04	154	1.28	99
100W	7.18	142	4.23	83.9
200W	3.53	143	1.71	69.4
300W	1.27	102	0.423	34.6
400W	0.88	64.7	0.192	14.14

Bearing faults are obtained by simply drilling holes in different parts (see Fig. 9) [34].

B. Experimental Results Analysis

Experimental tests focus on single-point defects which are localized ones and can be classified according to the following affected elements: outer raceway, inner raceway, ball, and bearing cage (see Fig. 9) [35].

An accurate fault detection is questionable without investigating the robustness against load variation and the relationship between the criteria and faults level. For that purpose, the proposed fault-detection criteria sensitivity has been evaluated according to load variations.

The measured stator currents are acquired at 10 kHz by data acquisition card. Further signal postprocessing is done off-line on a standard desktop PC using MATLAB. The following experimental validation is focused on the ball, inner raceway, and cage bearing failures for different load conditions.

1) *Ball bearing fault detection:* Figs. 10 and 11 illustrate the results of the spectral subtraction in the case of a ball bearing fault. These figures show the healthy and faulty stator current, and the resulting fault signature in time domain for an unloaded and loaded induction machine, respectively. This residue is used to compute the criteria in (5).

Table I reports on the criteria values. It depicts the criteria for healthy and faulty induction machine under different load conditions. These results clearly show the appropriateness of the proposed fault detection approach. To confirm this tendency, additional tests have been carried out to detect other bearing fault types.

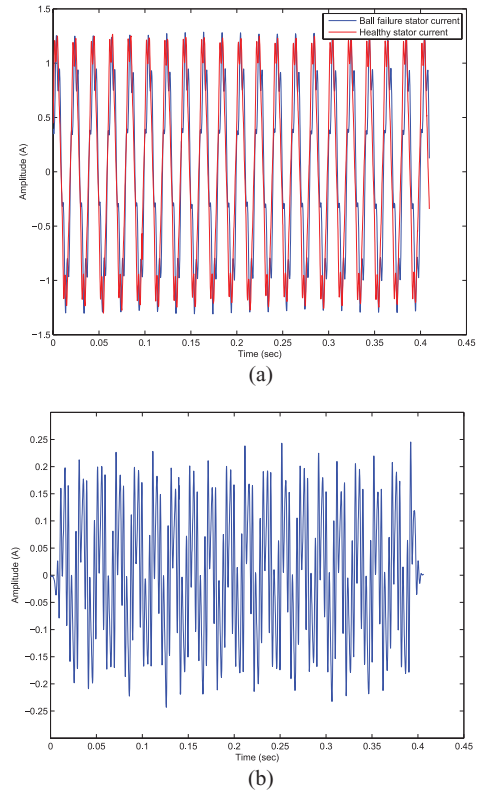

Fig. 10. Spectral subtraction on experimental stator currents for an unloaded machine. (a) Healthy and bearing failure stator currents. (b) Failure signature.

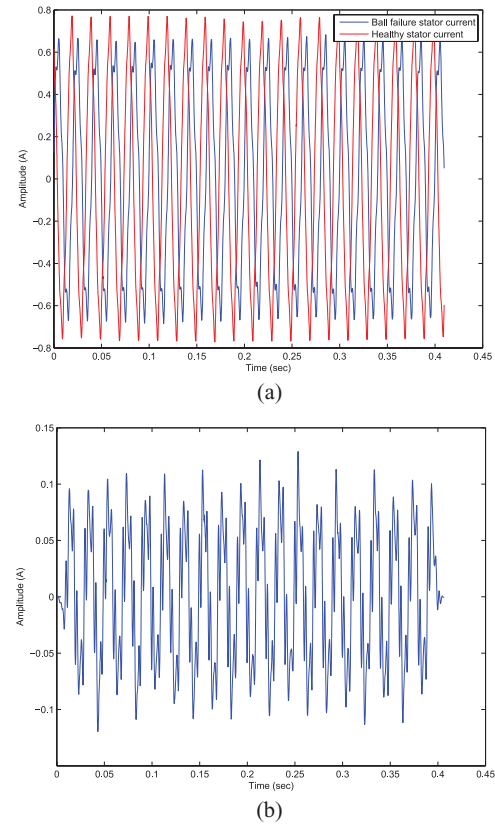

Fig. 11. Spectral subtraction on experimental stator currents for a 400W loaded machine. (a) Healthy and bearing failure stator currents. (b) Failure signature.

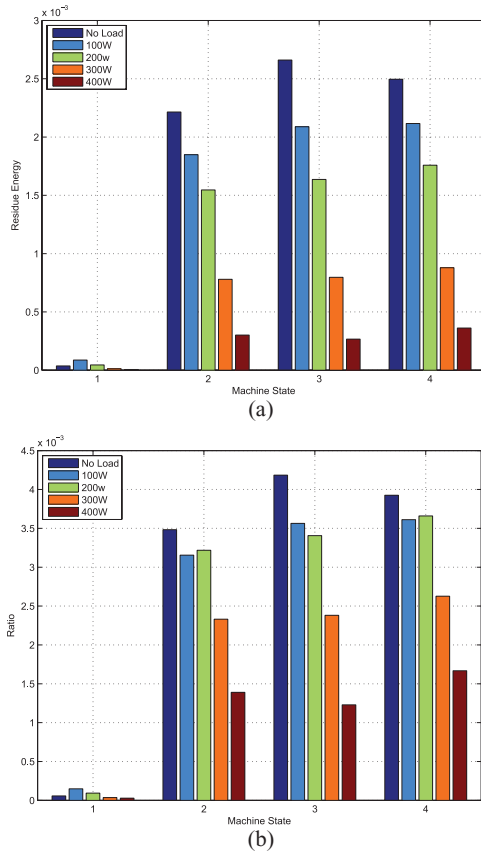

Fig. 12. Fault detection criteria for different load conditions and various faults (1: healthy, 2: inner race, 3: cage, 4: ball). (a) Residue energy. (b) Residue to healthy energy ratio.

2) *Experimental results for different bearing faults:* Fig. 12 shows the variation of the two criteria for different bearing fault namely inner race, cage, and ball faults.

According to these bar graphs, it can be concluded that spectral subtraction allows diagnosing the induction machine abnormal operating conditions regardless of load conditions. In fact, despite the criteria are load sensitive, they remain higher compared to a healthy machine even when the load increases. The criteria variation between the faulty and healthy case allows highlighting faulty operating conditions. It is clear that the energy ratio is more suitable for fault detection since it is less load sensitive.

3) *Comparison with DWT-based spectral subtraction:* The wavelet transform-based spectral subtraction could be performed by introducing some modifications in the previously described algorithm. In fact, the faulty and the database (healthy) stator current signals are first processed in order to remove the phase shift between the two signals. Afterward, the wavelet decomposition at level 10 is performed using Daubechies wavelet of order 32 for both signals. Then, the spectral subtraction is performed on the approximation signal and details. The inverse wavelet transform is then used in order to reconstruct the residue signal in the time domain. Finally, the two criteria proposed within this paper are computed. Fig. 13 illustrates the results for different operating conditions.

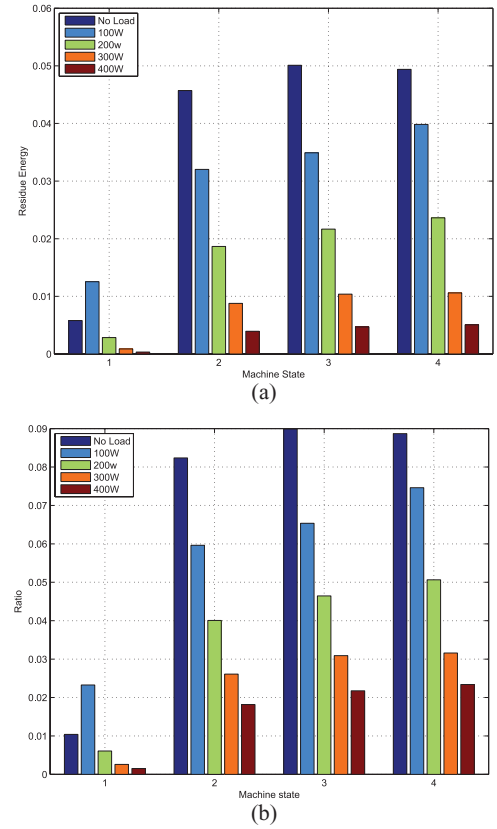

Fig. 13. Fault detection criteria based on discrete wavelet transform for different load conditions and various faults (1: healthy, 2: inner race, 3: cage, 4: ball). (a) Residue energy. (b) Residue to healthy energy ratio.

The same conclusions could be drawn from this bar chart as in the case of the use of *STFT*. The DWT-based spectral subtraction gives reliable results and allows to discriminate the faulty case from the healthy one since the criteria are higher in the case of faulty machine than in the case of the healthy one. It seems from these results that it is easier to discriminate the faulty machine by using the FFT-based spectral subtraction than the DWT-based spectral subtraction. This comparison allows to assert that the induction machine fault detection based on spectral subtraction may be performed using several time-frequency representations such as wavelet transform, Wigner-Ville distribution, Hilbert-Huang transform and many others.

C. Summary and Discussions

A simple fault metric has been evaluated here based on the instantaneous amplitudes of the extracted fault frequencies. This metric could be used to indicate a bearing fault at an early stage. Thresholds can be set to determine the severity of the fault and can provide an indication for prognosis purposes.

The spectral subtraction is based on the Fourier transform which means that the technique is limited by the Fourier transform resolution [36]. Despite this limitation, the proposed technique gives good results on simulated and experimental signals. Furthermore, comparison with DWT-based spectral subtraction has been performed. It demonstrates that in both cases the spectral subtraction is a well-suited technique to diagnose

abnormalities in the induction machine and especially bearing failures. This comparison proves the appropriateness of the spectral subtraction as medium for fault detection in induction machine through stator current analysis.

The general conclusions that can be drawn from these simulation and experimental results are the effectiveness of the proposed fault-detection approach. In the case where the stator current frequency content does not abruptly change, the proposed approach is assumed to be a well adapted tool to detect abnormal operating conditions in a nonstationary environment. In this case, a new baseline data should be retrieved and processed.

V. CONCLUSION

This paper dealt with the induction machine bearing faults detection. It has been proposed a new stator current-based fault-detection approach. Indeed, it has been suggested to monitor induction machine bearings by means of stator current spectral subtraction. The proposed technique effectiveness has been first confirmed using simulation data issued from a coupled electromagnetic circuits approach-based simulation tool. Afterwards, it has been validated by experiments on a 0.75-kW induction machine drive test bed. Other time-frequency tools could be used to perform spectral subtraction. It may perform better than the spectrogram since they have good resolution capabilities in time and frequency domains such as Wigner–Ville distribution and Continuous wavelet transform. Moreover, further investigations are required in order to propose a suited decision algorithm that may allow the automatic detection of a faulty machine using the fault detection strategy studied within this paper.

El Houssin El Bouchikhi was born in Khemisset, Morocco, in 1987. He received the Dipl.-Ing. and the M.Sc. degrees in automatic and electrical engineering from the National Polytechnic Institute of Toulouse (INP-ENSEEIH), Toulouse, France, in 2010. He is currently working toward the Ph.D. degree on offshore wind and marine current turbines condition monitoring with the University of Brest, Brest, France.

His current research interests include electrical machines fault detection and diagnosis through electrical quantities, especially under nonstationary operating conditions.

Vincent Choqueuse (M'08) was born in Brest, France, in 1981. He received the Dipl.-Ing. and the M.Sc. degrees in 2004 and 2005, respectively, from the Troyes University of Technology, Troyes, France, and the Ph.D. degree in 2008 from the University of Brest, Brest, France.

Since September 2009, he has been an Associate Professor with the Institut Universitaire de Technologie de Brest, University of Brest, and a member of the Mechanics and Systems Laboratory of Brest. His research interests include signal processing and statistics for diagnosis and multiple-input and multiple-output systems.

Mohamed El Hachemi Benbouzid (S'92–M'95–SM'98) was born in Batna, Algeria, in 1968. He received the B.Sc. degree in electrical engineering from the University of Batna, Batna, Algeria, in 1990, the M.Sc. and Ph.D. degrees from the National Polytechnic Institute of Grenoble, Grenoble, France, in 1991 and 1994, respectively, both in electrical and computer engineering, and the Habilitation à Diriger des Recherches degree from the University of Picardie "Jules Verne," Amiens, France, in 2000.

After receiving the Ph.D. degree, he joined the Professional Institute of Amiens, University of Picardie "Jules Verne," where he was an Associate Professor of Electrical and Computer Engineering. Since September 2004, he has been with the Institut Universitaire de Technologie de Brest, University of Brest, Brest, France, where he is a Professor of Electrical Engineering. His main research interests and experience include analysis, design, and control of electric machines, variable-speed drives for traction, propulsion, and renewable energy applications, and fault diagnosis of electric machines.

Dr. Benbouzid is a Senior Member of the Industrial Electronics, Industry Applications, Power Electronics, and Vehicular Technology Societies. He is an Associate Editor of the IEEE TRANSACTIONS ON ENERGY CONVERSION, the IEEE TRANSACTIONS ON INDUSTRIAL ELECTRONICS, the IEEE TRANSACTIONS ON SUSTAINABLE ENERGY, and the IEEE TRANSACTIONS ON VEHICULAR TECHNOLOGY. He was an Associate Editor of the IEEE/ASME TRANSACTIONS ON MECHATRONICS, from 2006 to 2009.
